***Abstract* – This paper investigates data for 9 common Alzheimer's Disease risk factors, from three different categories; Medical History, Lifestyle, and Demography. The dataset used consists of 185 normal control, 177 early mild cognitive impairment, 161 late mild cognitive impairment and 127 Alzheimer's Disease subjects.**
The initial experiment had training results of 0.92 sensitivity, 0.935 specificity and 0.771 precision. However, during the test stage the final output was 0.741 sensitivity, 0.515 specificity and 0.286 precision. The results of this experiment did not give a clear classification or definite predictive value. Involving more variables and underlying data could provide a better outcome. This paper is a part of a long-term study that focuses on the classification and ranking the importance of Alzheimer's Disease risk factors using Machine Learning predictive models and classifications techniques.

***Index Terms* - Alzheimer's Disease; Machine Learning; Classification; Dementia; ADNI.**

I. INTRODUCTION

Researchers from different fields such as biology, physiology, neurology, computer science and others have been exploring this, ultimately fatal disease, for decades. Although, there have been no major breakthroughs and scientists are still unsure of what is the actual cause of Alzheimer's Disease (AD) or have any cure for it, there is a valuable amount of knowledge and information that has been gained on the disease.

Like any disease, it is important that we know its risk factors and avoid them. Since scientists are still unsure of the actual cause of AD, however, there has been a lot of research to establish the risk factors for AD. General Health Practitioners (GP) would usually rely on diagnosing AD through its symptoms and several standards and procedures. However, AD shares most of its symptoms with other types of dementia; therefore, GPs can sometimes give a wrong diagnosis. The existence of these two protein "Plaques" and "Tangles" is what indicates and confirms the existence of AD [1].

False and inaccurate diagnoses are common when it comes to early diagnosis of dementia. This is because GPs rely on manual evaluation and mental examinations before they turn to brain imaging. It is difficult to manually diagnose AD, or any other types of dementia at an early stage before most of its symptoms are noticeable. Therefore, it is important to use computer analysis to analyse as much patient's data as possible for a better evaluation and more accurate diagnosis. First, it is important to express the complexity of AD progression, hence, why it's risk factors fall into multiple categories from biological risk factors to behavioural risk factors. The main categories of AD risk factors are age, genetics, medical history, lifestyle, and characteristics / demography. Health services providers and major research institutions around the world have provided a list of risk factors and declared some of them as high-risk factors, which poses potential development indication of AD. However, these risk factors do not mean that they are the real reasons behind the development of AD. This is because the pathology of AD progresses through different channels.

With AD, it is important to understand the behaviour or its risk factors and their interrelationship. This study can be viewed in three different phases. Phase one will provide a classified list of AD risk factors and their relevancy to pathology of AD with the use of machine learning tools, phase two will produce a similar outcome but based on manual evaluation from the existing research. The third phase will use the importance of the risk factors from both phases one and two to quest for predictive patterns of AD. The merge of the outcome from both phases one and two will boost the accuracy of the predictive patterns.

II. METHODS

Currently there has been little progress made in relation to developing a complete early diagnose approach of AD by using Intelligence Data Analytic and Machine Learning techniques for early prediction. The current work into prediction of AD relates to research using lifelogging technology to monitor memory decline or to diagnose the disease at a very late stage. According to the Alzheimer's Association there are no current working methods to diagnose AD at a very early stage and the "current diagnosis of Alzheimer's relies largely on documenting mental decline."[2] The methods used to diagnose AD are cognitive tests such as the Mini Mental Score Examination test and in some cases a

DOI 10.1109/HPCC/SmartCity/DSS.2018.00240

brain scan is required. Unfortunately, these methods detect AD at a very late stage when all of the symptoms appear.[3]
However, this research will focus on developing an evolving framework to effectively diagnosis and predict AD at a very early stage using the data collected for AD patients. The framework will continuously use large sets of related data to AD patient collected from multiple sources. The collected data will feed the framework with the input required to deploy computational modelling and machine learning techniques to predict and diagnose AD. The research will depend on collecting data from multiple existing datasets such as ADNI, and it will include collected data that related to DNA, dietary, medical history, lifestyle and any other related data linked to risk factors of AD.

Away from biological methods, this study will conclude with a working method for early diagnosis of AD. The proposed research aims to investigate AD with effective use of Machine Learning (ML) techniques to predict AD at a very early stage using its predictive risk factors. The overall target is to look for possible solutions by using data science, machine learning and artificial intelligence, in order to develop an intelligent data analytic framework to predict and visualise data for early diagnosis and prediction for people with AD.
The research aims to develop a framework consisting of the following stages; construction of a baseline dataset, deploying Machine Learning techniques on the dataset, increasing the dataset variables and deploying Deep Learning techniques to model high-level abstractions in the data as the datasets increases [4][5][6][7][8], tracking the changes and developing a weighting formula, then finally produce a computational method that will provide an early diagnostic tool of AD and help general participant with early decision-making.

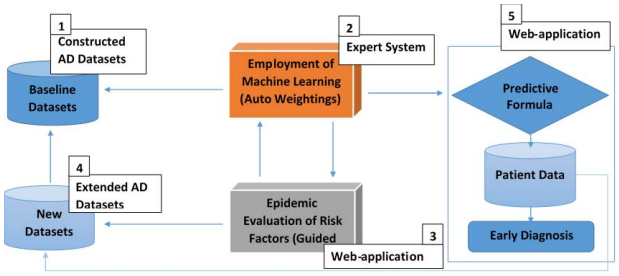

Fig.1. Diagram of proposed work.

Elaboration:

1. Subsets of data related to major risk factors of AD will be extracted from multiple existing (published) databases and constructed into a Machine Learning ready dataset.
2. Continuous learning technique will be employed to analyse the constructed dataset and provide feedback on the importance of the variables and AD risk factors. This part of the framework and the employment of ML techniques will be done using MatLab, R studio and other integration services.
3. A web-based sub-system will be developed to calculate guided weighting for each risk factor. This system will rely on validated discrete knowledge manually inputted by either system admin, or professionals through crowdsourcing. This will be used to influence the weighting used by ML techniques, as well as decision making when adding new variables to the dataset.
4. The feedback from both ML techniques and epidemic evaluation will be used to determine which new data needs to be collected and what variables should be added to the baseline dataset.[9]
5. Whilst constantly learning from the datasets, the predictive formula will continuously be update to provide as accurate prediction as possible. The prediction formula will feed into a live system in which live patient data will be stored. This part of the framework will keep track of patient records and trigger warnings when establish.[10]

III. FEATURE SELECTION

Feature selection widely used technique in research on big data; researchers explore domains with hundreds to tens of thousands of variables or features. Therefore, many feature selection techniques used to address these challenges in order to select relevant data and to remove irrelevant, redundant, and noisy information from the data [11]. There are many feature selection and these methods are categorized in three different classes based on how the selection algorithm and the model building are combined. The three classes of feature selection methods are; filter method, wrapper method and embedded method. A demonstration of how feature selection used to help researchers; Feature selection technique was employed in the work of Dimitrios Ververidis from the VTT Technical Research Centre of Finland. Titled: “Feature selection and time regression software: Application on predicting AD progress”[12].
In this work the data features will be extracted and selected in accordance to the work carried out on AD risk factors. The aim of this work is use AD risk factors as a mean to predict AD at an early stage before it progresses to severe stage. With this type of research Neural Network Classifiers will be used to identify the predictive AD risk factors. There are several risk factors for AD which will be used in this work. The work will use the ADNI datasets in the initial experiments, then it will use other datasets to expand the hunt for early prediction of AD.
ADNI collected data for subjects who are Normal Control (NC), Mild Cognitive Impairment (MCI), AD (AD), Significant Memory Concern (SMC), Early Mild Cognitive Impairment (EMCI) and Late Mild Cognitive Impairment (LMCI) patients. Initially, before data cleaning ADNI 2 had 1171 subjects; 343 NC, 204 AD, 230 EMCI, 159 LMCI, 131 MCI and 104 SMC. In the ADNI datasets there are over 63 tables containing rich amount of data for all of the patient

participated in the study. Each table has a large number of variables ranging between 11 to over 71. However, since this report is focused on early prediction of AD or pre-dementia stage, the experiments is carried out on data that relates to the behavioural markers and the variables selected are matching the features discussed in the risk factors section of this report.

The early prediction of AD will be attempted through a series of experiments on the ADNI datasets. First experiment will be carried out on ADNI 2 baseline data. The variables in this first experiment will be selected in accordance to AD risk factors as categorized by current research; medical history, lifestyle and demography. Three risk factors have been taken from each category. TABLE 1 lists the risk factors use as variables in this experiment.

Medical History	Lifestyle	Demography
Diabetes	Alcohol	Age
Cholesterol	Smoking	Education Field
Heart Disease	BMI	Race

TABLE 1: AD Risk Factors used in the experiment.

To start the experiments on the ADNI 2 dataset, the first step was to clean the data, removing rows with missing values, normalizing the values and converting strings to numeric values. However, after the performance of data cleaning the distance between the data volume for each class has changed and resulted for the data to be imbalanced. The graph below (Fig.2) shows an explore of the data after the deletion of subjects with missing data. This resulted in a very small number of subject who are classed as SMC compare to the rest of the classes, which, makes the dataset imbalanced.

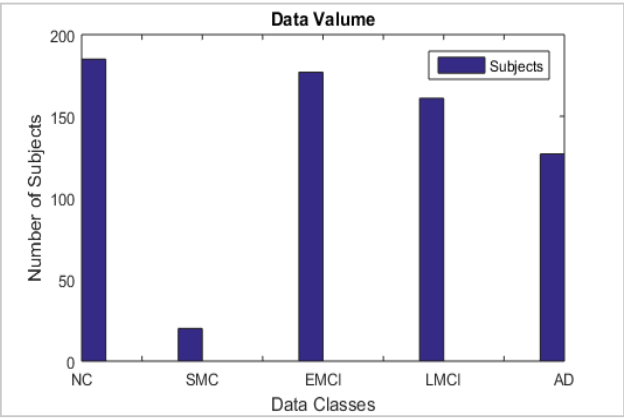

Fig.2 – ADNI Data Volume

IV. Data Analysis

Running the experiment on an imbalanced data will not give a correct accuracy as it will mislead the artificial agents to give insufficient results. To make the data more balance, all subjects with SMC class were removed from the dataset. The following graphs and tables show an overview of the final dataset thet will be used in the following experiments.

Class	Data Volume
NC	185
EMCI	177
LMCI	161
AD	127
Total	**650**

TABLE 2 – Final Dataset

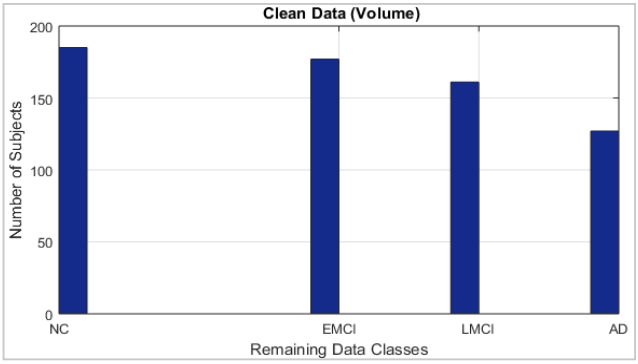

Fig.3 – Explore of Data Using MatLab Graphs

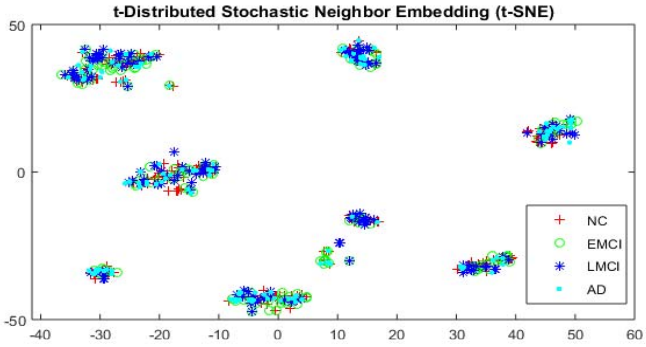

Fig.4 - Explore of Data Using t-SNE on MatLab

During this phase the number of subjected was reduced by almost 50%, now with a total remaining number of 650 subjects to be studied. TABLE 2 and the graph in Fig.3 give an overview of the dataset for each of the four remaining classes (Labels).

To explore the dataset suitably, different data analysis toolboxes on MatLab, MiniTab 16 were deployed, this includes t-Distributed Stochastic Neighbour Embedding (t-SNE), Principle Component Analysis (PCA), Independent Component Analysis (ICA), and Square Prediction Error (SPE). The t-SNE is a Machine Learning algorithm commonly used for dimensionality reduction in data visualization. t-SNE was apply on the dataset, giving the results showing in Fig.4, it shows mixed clusters detached apart. Ideally the perfect results that we had hoped for is that each cluster will contain a majority of one class. However, as shown in Fig.4; the clusters have almost equal mixture from all classes. Which, means that

the algorithm struggled to differentiate between the categories of the subjects. Though this algorithm also shows a large distance between the clusters which means on a dimensional level it managed to differentiate between the variables (risk factors).

Other useful methods used to explore and visualize this dataset is the Principal Component Analysis (PCA) and Independent Component Analysis (ICA), both Fig.5 - 7 illustrate the use of this technique on Matlab and MiniTab 16. PCA is used to emphasize the variation, dimensions reduction and bring out the strongest patterns in the dataset. ICA is a method for separating a multivariate signal into additive subcomponents.

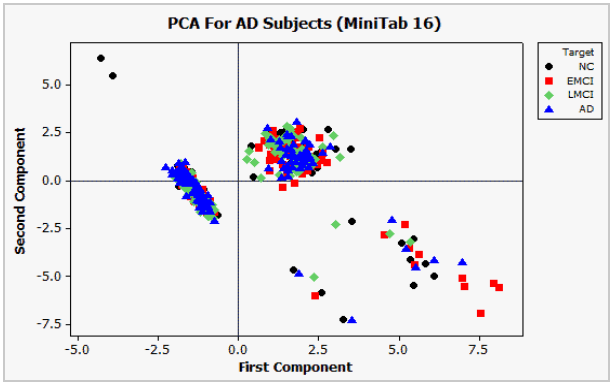

Fig.5 - Explore of Data Using PCA on MiniTab 16

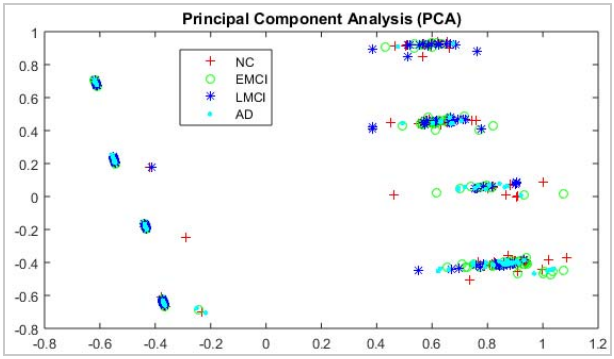

Fig.6 - Explore of Data Using PCA on MatLab

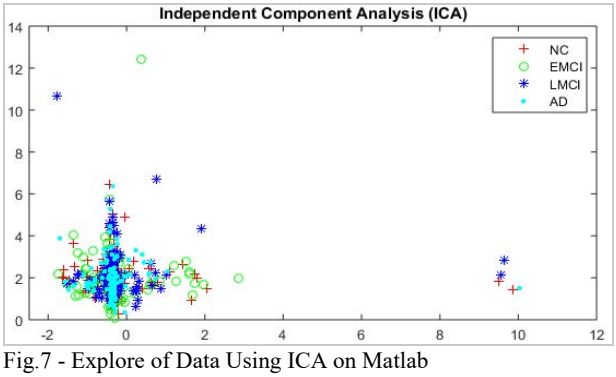

Fig.7 - Explore of Data Using ICA on Matlab

Furthermore, the data was explored using the Square Prediction Error (SPE) plot to measure the quality of a predictor. The graphs and coefficients result in TABLE 3 show an apparent indication that the type of study will be a nonlinear regression.

TABLE 3 –PCA Coefficient for Each Variable on MiniTab 16

The coefficient data shows an apparent indication that the experiment result of the predictors will not provide a clear outcome. From the data exploratory it is very unclear which variable is the highest predictive factor, which, shows that the classifiers might not give a very clear classification or definite predictive value. In this case future experiments involving more variables and underlying data will provide a better outcome.

TABLE 4 is a contingency table or commonly known as the confusion matrix table. This will be used as the evaluation technique for both training and test experiment results.

V. RESULTS

During both the training stage and test stage, the five different classifers where applied consecutively for approximatly 30 times for a better accuracy. The contrast between the outcome of the training experiment and the test experiment is very obvious. As expected the classifers have performed better during the training stage. Model H2 performed the best while other classifers did not have dramatic difference during the test stage. Fig. 9 – 10 and TABLE 5 show the out come of the test experiments. From a constructive prospective the initial investigation provide a needed foundation to darw a roadmap for future work and it has become apparent that more variable related to AD risk factors are required to improve the accuracy of the classifers.

VI. DISCUSSION

According to the Alzheimer's Association there are no current working methods to diagnose Alzheimer's Disease at a very early stage and the "current diagnosis of Alzheimer's relies largely on documenting mental decline."[2] The method used to diagnose Alzheimer's Disease is by using the Mini Mental Score Examination test and in some cases a brain scan. Unfortunately, these methods detect Alzheimer's Disease at a very late stage when all of the symptoms appear.[3] However, the more knowledge gain on Alzheimer's Disease, the closer scientists get to solving its mysterious cause.

Identifying the causes of Alzheimer's disease is a very challenging task as it is caused by multiple risk factors. The use of Machine Learning to assist in the diagnosis and prediction process of Alzheimer's disease will help us learn more about the disease and its behaviour. Using Machine Learning algorithms computers can analyse and extract patterns from multivariable datasets far more quickly compare to humans. Early prediction of Alzheimer's disease is a very challenging path of study due to the fact that there is a limited amount of knowledge revealed on its

underlying causes. However, that does not mean it is not possible. Alzheimer's disease is like any other disease; it is caused by abnormal genetic mutation of the cells. At some point in the life of an Alzheimer's disease subject, they must have been exposed overtime to risk factors that are responsible to the development of Alzheimer's disease. The apparent element in the study of Alzheimer's disease, is that beside being caused by genetic disorder from birth it is also caused by overtime genetic mutation as a side effect of multiple high-risk factors such as lifestyle, medical vascular diseases and genetics type.

This paper is a part of a long-term study that focuses on the classification and ranking the importance of Alzheimer's Disease risk factors using Machine Learning predictive models and classifications techniques. We carried out an initial experiment to examine the use of Machine Learning technique to investigate Alzheimer's disease. We used five different Machine Learning Classifiers; Random Oracle Model, Random Forest Classifier, Fischer Discriminate Analysis, Multi-Layer Perceptron and Linear Neural Networks. 80% of the data was used for training the classifiers and 20% was used to test the performance of the classifiers. The baseline dataset is a de-identified multivariable Alzheimer's Disease patient's data, provided by the ADNI (Alzheimer's Disease Neuroimaging Initiative), to illustrate an effective use of data analysis to investigate Alzheimer's Disease biological and behavioural risk factors. The data contained information on 9 common Alzheimer's Disease risk factors, from three different categories; Medical History, Lifestyle, and Demography. The dataset has four different classes; 185 normal control,177 early mild cognitive impairment, 161 late mild cognitive impairment and 127 Alzheimer's Disease subjects.

The five different classifers where applied consecutively for approximatly 30 times for a better accuracy. However, the results were as expected, the experiment result of the classifiers might not give a very clear classification or definite predictive value, but we expect to see which classifier performed best on the data and which risk factor is more likely to be a predictive factor to the rest of the dataset variables. Unfortunately, we could not tell which variable is potentially a high-risk factor in this experiment. However, we have notice that the Fischer Discriminate Analysis classifier have perform better compare to other classifiers during both training and testing phase. The Fischer Discriminate Analysis classifier give training results of 0.92 sensitivity, 0.935 specificity and 0.771 precision. During the test stage the final output of this classifier was 0.741 sensitivity, 0.515 specificity and 0.286 precision. The results of this experiment did not give a clear classification or definite predictive value. Which means involving more variables and underlying data could provide a better outcome.

This initial investigation was purely used as an approach to begin a long journey into early prediction of Alzheimer's Disease. The outcome of the work carried out to date in this field, supports the need of involving more underlying data related to both behavioural and biological markers of Alzheimer's Disease. The overall aim of our study is to improve the accuracy of early diagnosis of Alzheimer's Disease, and build the foundation of a predictive dynamic framework, it will be used for early prediction of Alzheimer's Disease, collection of valuable relevant data, support Healthcare Professionals with diagnosis decision-making and provide an insight into Alzheimer's Disease.

ACKNOWLEDGMENT

The data used in this research was provided by Alzheimer's Disease Neuroimaging Initiative (ADNI). We thank our Professor Danielle J Harvey from University of California, Davis who provided insight and expertise that greatly assisted us in understanding and using the datasets. *Data used in preparation of this article were obtained from the Alzheimer's Disease Neuroimaging Initiative (ADNI) database (adni.loni.usc.edu). As such, the investigators within the ADNI contributed to the design and implementation of ADNI and/or provided data but did not participate in analysis or writing of this report. A complete listing of ADNI investigators can be found at: http://adni.loni.usc.edu/wp-content/uploads/how_to_apply/ADNI_Acknowledgement_List.pdf

Data collection and sharing for this project was funded by the Alzheimer's Disease Neuroimaging Initiative (ADNI) (National Institutes of Health Grant U01 AG024904) and DOD ADNI (Department of Defense award number W81XWH-12-2-0012). ADNI is funded by the National Institute on Aging, the National Institute of Biomedical Imaging and Bioengineering, and through generous contributions from the following: AbbVie, Alzheimer's Association; Alzheimer's Drug Discovery Foundation; Araclon Biotech; BioClinica, Inc.; Biogen; Bristol-Myers Squibb Company; CereSpir, Inc.; Cogstate; Eisai Inc.; Elan Pharmaceuticals, Inc.; Eli Lilly and Company; EuroImmun; F. Hoffmann-La Roche Ltd and its affiliated company Genentech, Inc.; Fujirebio; GE Healthcare; IXICO Ltd.; Janssen Alzheimer Immunotherapy Research & Development, LLC.; Johnson & Johnson Pharmaceutical Research & Development LLC.; Lumosity; Lundbeck; Merck & Co., Inc.; Meso Scale Diagnostics, LLC.; NeuroRx Research; Neurotrack Technologies; Novartis Pharmaceuticals Corporation; Pfizer Inc.; Piramal Imaging; Servier; Takeda Pharmaceutical Company; and Transition Therapeutics. The Canadian Institutes of Health Research is providing funds to support ADNI clinical sites in Canada. Private sector contributions are facilitated by the Foundation for the National Institutes of Health (www.fnih.org). The grantee organization is the Northern California Institute for Research and Education, and the study is coordinated by the Alzheimer's Therapeutic Research Institute at the University of Southern California. ADNI data are disseminated by the Laboratory for Neuro Imaging at the University of Southern California.
